Speciation in flow reactor

## ABSTRACT

Alkylated cycloalkanes are vital components in gasoline, aviation, and diesel fuels; however, their combustion chemistry has been less investigated compared to other hydrocarbon classes. In this work, the combustion kinetics of *n*-propylcyclohexane (*n*-Pch) was studied across a range of experiments including pressurized flow reactor (PFR), jet stirred reactor (JSR), shock tube (ST), and rapid compression machine (RCM). These experiments cover a wide range of conditions spanning low to intermediate to high temperatures, low to high pressures at lean to rich equivalence ratios. Stable intermediate species were measured in PFR over a temperature range of 550–850 K, pressure of 8.0 bar, equivalence ratio ( $\phi$ ) of 0.27, and constant residence time of 120 ms. The JSR was utilized to measure the speciation during oxidation of *n*-Pch at  $\phi$  of 0.5–2.0, at atmospheric pressure, and across temperature range of 550–800 K. Ignition delay times (IDTs) for *n*-Pch were measured in the RCM and ST at temperatures ranging from 650 to 1200 K, at pressures of 20 and 40 bar, at  $\phi = 0.5, 1.0$ . In addition, a comprehensive detailed chemical kinetic model was developed and validated against the measured experimental data. The new kinetic model, coupled with the breadth of data from various experiments, provides an improved understanding of *n*-Pch combustion.

## 1. Introduction

### 1.1. Background

The aviation industry consumes a substantial quantity of hydrocarbon-based jet fuel every year, which adds significantly to global carbon emissions, and since 2013 alone emissions from aviation operations have risen by 26% [1]. Reduction of these emissions is an ongoing exercise, and it relies on the refinement of existing propulsion technologies involving combustion engines and fuel blends.

Several measures are adopted to improve aviation engines' performance and fuel efficiency, such as enhancements in the design of the compressor, combustor, and fuel injection systems, valves

etc. [2–4]. On the fuel side, blending of biofuels to jet fuels [3,5,6] and enhancing the understanding of jet fuel's base component combustion characteristics which is also the focus area of this work. Typical jet fuels are a complex mixture of hydrocarbons and contains ~21% alkylated cycloalkanes, by mass, by global average survey estimates [7]. These alkylated cycloalkanes include methylcyclohexane (MCH), ethylcyclohexane (ECH), *n*-propylcyclohexane (*n*-Pch), *n*-butylcyclohexane (*n*-Bch) etc. Studies focussing on MCH, ECH, and *n*-Bch are available in significant detail in literature elucidating their combustion properties and detailed kinetic model development. However, studies detailing *n*-Pch combustion are limited in number and scope, and they do not present comprehensive investigations as typically available in the literature for other cycloalkanes. In the next section, a detailed review of combustion studies of alkylated cycloalkanes is provided.

## 1.2. Literature survey

### 1.2.1. Methylcyclohexane (MCH)

Han et al. [8] measured ignition delay of MCH and n-hexane blends in a constant volume reactor similar to an ignition quality tester at 20 bar and 820–920 K. Also, the effect of fuel injection parameters on heat release rate and ignition delay time were investigated. In another study Hong et al. [9] measured ignition delay times of MCH and ECH in a shock tube at low pressures of 1.5 and 3.0 atm, temperatures of 1280–1480 K, and  $\varphi = 0.5, 1.0$ . Pitz and coworkers [10] reported ignition delay measurements of MCH in a rapid compression machine (RCM) at 10–20 bar, 650–1100 K for stoichiometric mixtures and also proposed a kinetic mechanism. Vanderover et al. [11] conducted ignition delay measurements for MCH in a shock tube at pressure range of 10.8–69.5 atm, temperature range of 881–1319 K, and  $\varphi = 0.25, 0.5, 1.0$ . Similarly, Vasu et al. [12] also measured ignition delay time of MCH in shock tube over a wide pressure range in a shock tube from 1 to 50 atm, 795–1560 K,  $\varphi = 0.5$ –2.0. Weber et al. [13] performed ignition delay measurements in an RCM at 50 bar, 690–900 K,  $\varphi = 0.5$ –1.5. Humer et al. [14] measured flame extinction and autoignition of MCH and other fuels in a laminar non-premixed flow in the counterflow configuration. In addition, a reduced kinetic mechanism was proposed which adequately predicted the experimental data. In 2019, Bissoonauth et al. [15] conducted an oxidation and pyrolysis study in jet stirred reactor across an extensive range of pressures (1–50 bar) and temperatures (500–1100 K) at three different experimental facilities and measured the concentrations of intermediates and end products. Narayanaswamy et al. [16] developed a detailed kinetic mechanism in the low to high-temperature region and improved the model using experimental data from the literature. MCH has also been studied in a Cooperative Fuels Research (CFR) engine by Yang and coworkers [17] by varying the compression ratio from 4 to 15. These investigations were conducted at  $\varphi = 0.25$  and two inlet temperatures 120 and 200 °C and exhaust gasses were analyzed and various conjugated alkenes and cyclic oxygenates were measured. Wang et al. [18] studied MCH pyrolysis using synchrotron vacuum ultraviolet photoionization mass spectrometry at the National Synchrotron Radiation Laboratory (NSRL), Hefei, China. Molecular-beam sampling was used to analyze the species formed during pyrolysis in a flow reactor. The authors also studied oxidation of MCH in premixed flames and several pyrolysis and flame intermediates were quantified. Orme et al. [19] studied oxidation and pyrolysis of MCH in a shock tube at experimental conditions of 1–4 bar, 1200–2100 K and  $\varphi = 0.5, 1.0, 2.0$ , and proposed a detailed kinetic model. In another work, a mechanism describing high temperature combustion of a range of n-alkanes up to n-dodecane and cyclohexane, and methyl-, ethyl-, n-propyl and n-butyl-cyclohexane was developed by Wang and coworkers as Jetsurf 2.0 [20]. Wu et al. [21] measured laminar flame speeds of MCH at high pressure of 10 atm and temperature of 353 K and at range of equivalence ratios  $\varphi = 0.7$ –1.7.

### 1.2.2. Ethylcyclohexane (ECH)

Husson et al. [22] conducted a jet stirred reactor study at 1 atm, 500–1100 K, and  $\varphi = 0.25, 1, 2$  measuring speciation during oxidation of ECH. More recently, a shock tube was used to measure ignition delay times for ECH and n-Pch at atmospheric pressure,  $\varphi = 0.5, 1.0$ , and 2.0, temperatures of 1110–1650 K, and with a fixed fuel concentration of 0.5% [23]. Ignition simulations were performed using three previously developed and published chemical kinetic mechanisms which yielded acceptable agreement with the shock tube measurements at the studied equivalence ratios. Tian et al. [24] studied the ignition of ECH in a shock tube at 1.1–10 atm, 1000–1700 K, and  $\varphi = 0.5$ –2.0. Wang et al. [25] studied pyrolysis of ECH in a flow reactor at atmospheric pressure across

temperature range of 900–1100 K and quantified the products using gas chromatography and synchrotron vacuum ultraviolet photoionization mass spectrometry. Wang et al. [26] then further expanded their investigation by measuring species for both oxidation and pyrolysis of ECH at low pressures of 30, 150 and 760 Torr.

### 1.2.3. Propylcyclohexane (n-Pch)

Ignition of n-Pch has been studied in an RCM at lean conditions at 620–930 K, 4.5–13.4 bar, and  $\varphi = 0.3, 0.4, 0.5$  by Crochet [27]. Dubois et al. [28] studied the ignition characteristics of n-Pch in a shock tube at 10–20 bar, at higher temperature range of 1250–1800 K,  $\varphi = 0.2$ –1.5, and flame speeds in constant volume spherical bomb at 1 bar, 403 K,  $\varphi = 0.6$ –1.75. In addition, they also assembled a kinetic mechanism. Guo et al. [29] formulated a high-temperature n-Pch mechanism using their inhouse code ReaxGen and compared it with data from shock tubes, laminar flames, jet stirred reactors from literature. Ristori et al. [30] measured speciation during oxidation of n-Pch in JSR at atmospheric pressure, 950–1250 K,  $\varphi = 0.5$ –1.5 and also developed a kinetic model. Farid [31] and Corrubia [32,33] at Drexel university measured n-Pch intermediate species in a Pressurized Flow Reactor (PFR) at 8 atm and a range of temperatures from 550 to 850 K. Pousse et al. [34] studied flame structures of methane flames doped with n-PCH and also proposed a kinetic model for n-Pch combustion.

### 1.2.4. Butylcyclohexane (n-Bch)

Oxidation of blends of n-Bch and heptane has been studied in both a shock tube and rapid compression machine by Conroy [35]. The ignition delay time measurements were made at 1–50 atm, 580–1550 K, and  $\varphi = 0.3, 0.5, 1.0$  and 2.0. In another study, Mao et al. [36] conducted an extensive RCM investigation of n-Bch ignition characteristics at 10, 15, 20 bar; 612–1374 K and  $\varphi = 0.5, 1.0, 1.5$ . The oxidation of n-Bch was studied in PFR [37, 38] with an initial fuel molar fraction of 1082 ppm ( $\varphi = 0.38$ ), the temperature of 600–820 K, pressure of 8 atm, and residence time of 120 ms. Detailed intermediate speciation with a GC / MS revealed straight-chain species (i.e. alkenes and aldehydes) and various cyclic compounds (i.e., cycloalkenes, ketone-substituted cycloalkanes and several two ring cyclic structures). The work from Drexel also developed a semi-detailed n-Bch low-temperature oxidation mechanism that captured the measured PFR reactivity trends which were characterized by low temperature increasing reactivity and NTC behavior decreasing overall reactivity.

An experimental and modelling study using shock tubes and a rapid compression machine was performed with n-Bch by Pitz and coworkers [39] at temperatures of 630–1420 K, pressures of 10, 30, 50 atm and  $\varphi = 0.3, 0.5, 1.0, 2.0$ . In addition, a detailed n-Bch chemical kinetic model was developed to simulate its ignition at both low and high temperatures. The experimental ignition delay times were used to improve the chemical kinetic model. The authors concluded that rate constant parameters developed from recent ab initio calculations provided better predictions of experimental ignition delay time data than the estimated rate constant parameters based on analogies to other molecules [40]. Recently, Zhang and coworkers [41] conducted experimental ignition delay measurement of n-Bch in shock tube at 2, 5, 15 atm; 707–1458 K;  $\varphi = 0.5, 1.0, 2.0$ . Mao and coworkers [36,42] conducted studies on n-Bch using rapid compression machine and shock tube measuring ignition delay at 10–20 bar, 612–1374 K,  $\varphi = 1.0, 1.5$  and speciation during oxidation in flow reactor 1 bar, 650–1075 K,  $\varphi = 1.0, 1.5$ . In addition, they also proposed a detailed kinetic mechanism. Hong et al. [9] compared ignition delay of cyclohexane, MCH, and n-Bch at 1.5, 3 bar, 1280–1480 K,  $\varphi = 0.5, 1.0$ . Ali et al. [43] studied thermal decomposition of n-Bch at 0.01–1 atm, 800–2100 K. Liu et al. [44] studied ignition of various cyclohexanes including n-Bch in counterflow burner at 1 bar and 373 K.

It is evident from the literature review that *n*-Pch warrants further combustion investigation, especially at low to intermediate temperatures and higher pressures. Besides, previous studies have not proposed a detailed chemical kinetic model for *n*-Pch combustion for wide range of pressures, temperature and equivalence ratios elucidating ignition and speciation characteristics.

To this end, this work presents a detailed examination of combustion chemistry of *n*-Pch wherein ignition delay time (IDT) measurements have been made at low to high pressures in RCM and shock tube (ST). Intermediate speciation studies were conducted in a jet stirred reactor (JSR) and pressurized flow reactor (PFR) experiments. Further, a detailed chemical kinetic model has been proposed and validated against the acquired experimental dataset.

The experimental measurements in the JSR, ST, and RCM were conducted at King Abdullah University of Science and Technology (KAUST). The JSR facility at KAUST was utilized to measure speciation during oxidation of *n*-Pch at  $\phi = 0.5, 1.0, 2.0$ , atmospheric pressure, and in the temperature range of 550–800 K. IDT's of *n*-Pch mixtures were measured in an RCM and ST for low to high temperatures ranging from 650–1200 K, at higher pressures of 20 and 40 bar, and  $\phi = 0.5, 1.0$ . Speciation measurements were conducted in PFR facility at Drexel University in the temperature range of 550–850 K and pressure of 8.0 atm. A detailed chemical kinetic model for *n*-Pch was developed to describe ignition characteristics, fuel consumption pathways and product species formation. Comparisons between results computed with the developed model and the measured experimental data are presented, and the kinetics of *n*-Pch combustion are discussed.

## 2. Chemical kinetic modeling

This section discusses the chemical kinetic model of *n*-Pch proposed in this work which is consistent with earlier works of Wang et al. investigating flame and pyrolysis kinetics of MCH [18] and ECH [26]. The developed mechanism has 1442 species and 6397 reactions, and the base C<sub>0</sub>–C<sub>4</sub> chemistry is described by Aramcomech 2.0 [45].

In the following section, details of important reaction classes in the low-temperature and high-temperature mechanism and the estimation of thermochemistry and kinetic rate parameters are discussed.

### 2.1. High-Temperature reactions

#### 2.1.1. Unimolecular reactions of *n*-Pch

The uni-molecular reactions of *n*-Pch include three dissociation and seven isomerization pathways, as shown in Fig. 1. As in Wang's ethylcyclohexane mechanism [26], H elimination reactions are not included due to their higher activation energies than competing decomposition and isomerization channels [26]. The rates for these reactions were assigned based on analogous pathways from the ethylcyclohexane mechanism [26], which in turn, were calculated by Zhang et al. [46] using RRKM/master equations. The uni-molecular decomposition leads to the formation of ethylcyclohexyl, methylcyclohexyl and cyclohexyl radicals which further undergo  $\beta$ -scission to produce alkenyl and alkyl species. Specifically the rates of pathways leading to methyl- and ethylcyclohexyl radicals were adopted from analogous pathways of *n*-butane combustion from Oehlschlaeger et al. [47]. The isomerization channels lead to the formation of various straight and branched C-9 alkenes, which are subsequently consumed through H-atom abstraction and  $\beta$ -scission channels to smaller species.

Fig. 1. Unimolecular reactions of *n*-propylcyclohexane.

Fig. 2. *n*-propylcyclohexane radicals produced after H-atom abstraction from various sites.

### 2.2. Hydrogen abstraction reactions

Hydrogen abstraction from the fuel molecule is an essential class of reactions responsible for fuel consumption. In the mechanism, *n*-Pch undergoes initial H-atom abstraction by various species (e.g., O<sub>2</sub>, O, OH, HO<sub>2</sub>, H, CH<sub>3</sub>), leading to the production of seven distinct fuel radicals as shown in Fig. 2. The majority of H-atom abstraction rates by different species leading to fuel radicals R1, R2 and R3 were adopted from Jetsurf 2.0 [20]. In addition, some rates from literature were also used at these sites (R1, R2, R3) to improve the performance of the model. Specifically, abstraction by OH radical at sites R2 and R3 were adopted from experimentally measured rates from Badra et al. [48] and abstraction by H radical at site R2 was adopted from Liu et al. [49]. The rates from Badra et al. [48] were tuned within 60% of published rates while the rate from Liu et al. [49] was increased by a factor of 2. The rate of H atom abstractions by radicals O, H, CH<sub>3</sub>, O<sub>2</sub>, HO<sub>2</sub> from the sites on the ring (R4, R5, R6, R7) were adopted from Wang's ECH work [26] where the rates of abstraction by H radical were increased by a factor of 2. Rate of attack by OH on the secondary sites of the ring (R5, R6, R7) were adopted from Weber et al. [13] and were also tuned within a factor of 2, while the rate for site R4 was adopted from Wang et al. [18,26].

There is still lack of reliable theoretical and experimental reaction rate data for *n*-Pch combustion and hence modifications are needed before rates from analogous compounds could be adopted. In this case, reaction rates were tuned to improve ignition prediction of the mechanism in the intermediate and high temperature

Fig. 3. Consumption of alkenes produced via unimolecular reactions of n-propylcyclohexane.

region and the tuned reactions were identified by conducting sensitivity analysis.

The alkyl radicals produced were consumed through  $\beta$ -scission reactions leading to the formation of alkenes and alkenyl species.

### 2.3. Consumption of alkanes and alkenes

Unimolecular reactions of *n*-Pch leads to formation of seven linear and branched alkenes (Fig. 1). These alkenes are then consumed through allylic H-atom abstraction reactions followed by  $\beta$ -scission leading to formation of miscellaneous species and di-enes. These di-enes are further consumed by H-atom abstraction reactions and  $\beta$ -scission reactions to produce smaller species already present in the base mechanism or the mechanism of ECH [26]. The reaction rates of allylic H-atom abstraction and  $\beta$ -scission reactions were adopted from Wang et al. [18,50]. These consumption pathways are exhibited in Fig. 3 for various H-atom abstraction and  $\beta$ -scission pathways. Due to relatively higher activation energy barrier of these reactions, these species are expected to be formed in minor quantities hence a simplified consumption scheme by allylic H-atom abstraction is considered, however this simplification could be revisited when more accurate rates are available for production of these species.

Another set of alkenyl and alkyl species along with alkenes are produced via  $\beta$ -scission of fuel radicals which include ring-opening pathways. They undergo  $\beta$ -scission to smaller alkenes, as shown in Fig. 4. The rates for these  $\beta$ -scission reactions were adopted from different alkanes and alkene species with the analogous position of the double bond, chain length and radical sites from Wang et al. [26].

### 2.4. Low-Temperature mechanism

The first step in low-temperature oxidation chemistry is the addition of the oxygen molecule ( $O_2$ ) to the fuel radicals (R1-R7) leading to the formation of seven alkylperoxy radicals ( $RO_2$ ), as shown in Fig. 5 for R6. The reaction rates for these steps have been

Fig. 4. Alkenyl radical decomposition of n-propylcyclohexyl radical.

adopted based on Curran et al. [51], which are originally based on works of Lenhardt et al. [52] and Atkinson et al. [53] for the propyl branch while the rates on the ring are from Fernandes et al. [54]. The next major step in the low-temperature chain branching step is the isomerization of alkylperoxy radicals ( $RO_2$ ) to hydroperoxy

Fig. 5. Low-Temperature branching pathways for *n*-Pch.

alkyl radicals (QOOH). These reactions proceed via an internal H-atom transfer via 5, 6, 7 and 8 membered transition state rings. Fig. 5 depicts this pathway with a five, six and seven-membered transition state. The rates for this class of reactions were based on analogies for alkanes by Sarathy et al. [40], which are based initially on the work of Curran et al. [51]. The internal H-atom transfer leads to creating a carbon centered radical, which undergoes second O<sub>2</sub> molecule addition, leading to hydroperoxy alkylperoxy radicals (O<sub>2</sub>QOOH). These reaction rates are adopted from Lenhardt et al. [52] and Curran et al. [51]. There are other competing pathways leading to the formation of alkenes and cyclic ethers leading to accumulation of relatively stable species hence making the chemical system less reactive. The rates for these reactions were adopted from Curran et al. [51].

Recently some studies have also demonstrated pathways leading to addition of third O<sub>2</sub> [55,56] molecule to P(OOH)<sub>2</sub> which is produced by intramolecular isomerization of O<sub>2</sub>QOOH. These pathways are shown to have significant impact on low temperature reactivity of long chain alkanes but at present we do not have reliable rate constants to include such pathways in the mechanism.

The hydroperoxy alkylperoxy radicals isomerizes to form ketohydroperoxides (carbonyl hydroperoxide), and the rates are adopted from Curran et al. [51,57]. The last step in the low-temperature branching pathway is the decomposition of ketohydroperoxide producing sets of radicals and stable species. These reactions are assigned as irreversible and forward rates have been adopted from Sarathy et al. [40]. There are multiple other classes of reactions in the low-temperature oxidation scheme involving chain propagation and termination steps, and the rates have been adopted by analogous sites and structures from Sarathy et al. [40].

In addition to a detailed description of the chemistry of *n*-Pch in the low and high-temperature region, this mechanism also includes the oxidation pathways leading up to *n*-propylbenzene and its consumption as proposed by Darcy et al. [58].

## 2.5. Thermochemistry

The thermochemistry for multi-ring species was calculated in this work using quantum chemical methods with the Gaussian 09 [59] suite of programs. During these calculations, merged ring structures are optimized with B3LYP/6-31+G(d,p) [60,61] level of theory, and then the total energies are determined with CBS-QB3 [62]. Entropy and heat capacity contributions as a function of temperature are then determined using moments of inertia, vibra-

tion frequencies, symmetry, electron degeneracy, number of optical isomers and the known mass of each species. SMCPS [63] program is applied to calculate the contributions of translation, external rotation, and vibrations by using standard formulas from statistical mechanics. Vibrational frequencies are scaled by a factor of 0.964 [64] to calculate standard entropy and heat capacity at the B3LYP/6-31+G(d,p) level of calculation. Rotator [65] program is used to calculate the contribution from the corresponding internal rotor torsion frequencies. In this work, a ten-parameter Fourier series function is used as a torsional potential curve to estimate free internal rotation contribution. The species for which thermochemistry has been calculated are shown in Fig. 6, and detailed function and parameters are shown in the supporting material. Thermochemistry for simpler species has been calculated with Benson's group additivity approach [66] using THERM software [67] as implemented on CloudFlare [68].

## 3. Experimental measurements and methodology

### 3.1. Pressurized Flow Reactor(PFR)

The Drexel University Pressurized Flow Reactor (PFR) used in this study is a turbulent flow reactor designed to study the low to intermediate temperature oxidation of hydrocarbons, shown schematically in Fig. 7. The design achieves reduced gradients in temperature and the flow field to allow the use of plug flow assumptions [69,70] for data analysis and modelling. The PFR contains a 22.5 mm ID, 40 cm long quartz reactor tube to provide an environment where surface reactions are negligible within a stainless steel pressure vessel rated to a maximum of 20 bar; however, 8 bar was selected for this study to allow comparison to the work of Natelson et al. [38]. The annular volume between the quartz reactor tube and the pressure vessel is at the same pressure as the reaction chamber. During a typical oxidation experiment, the oxidizer stream (composed of high purity nitrogen (purity = 99.9%) and high purity oxygen (purity = 99.994%)) is mixed with high-pressure pre-vaporized fuel/nitrogen in an opposed jet annular mixing nozzle at the inlet to the quartz reactor tube. For the maximum as designed PFR operating conditions (<1000 K, <20 bar), a nominal mixing time was calculated to be 1.25 ms [69]. A water-cooled, borosilicate glass-lined stainless-steel sample probe extracts and quenches samples from the centerline of the quartz reactor tube.

A direct transfer controlled cool down (DT-CCD) operational procedure was used to minimize the time between sample collection and analysis of stable intermediate species in the gas chromatograph (GC) / mass spectrometer (MS) / flame ionization detector (FID). The DT-CCD method developed by Kurman et al. [71] produced a carbon balance of 90% at 550–850 K.

During an oxidation experiment, the PFR was heated to the maximum desired reaction temperature of approximately 850 K when a syringe pump injected fuel into a 300 °C nitrogen stream that ensured complete fuel vaporization. The fully vaporized fuel/nitrogen mixture rapidly mixed with the oxidizer stream in an opposed jet annular mixing nozzle, with a nominal mixing time of 1.25 ms. The PFR experiment flow rates were: 0.750 ml/min *n*-Pch, 8.40 slpm O<sub>2</sub>, 161.2 slpm N<sub>2</sub> for the oxidizer stream, plus 20.00 slpm N<sub>2</sub> for *n*-Pch fuel vaporization. The relatively large nitrogen bulk flow rate acted as a diluent to limit the temperature rise due to heat release to a maximum of approximately 10 K at maximum reactivity as measured from the mixing nozzle to the sample probe. After the system stabilized, the sample probe was positioned for a reaction time of 120 ms, and the first sample was withdrawn for analysis. Stable intermediate species in the sample were identified and quantified with the GC/MS/FID and CO/CO<sub>2</sub>/O<sub>2</sub> detector. During the analysis time for the first sample, the PFR

Fig. 6. List of species for which thermochemistry data has been calculated in this work using quantum chemistry approach.

Fig. 7. Schematic of the Drexel Pressurized Flow Reactor facility.

temperature was gradually reduced to the next selected sample temperature. The probe was repositioned to maintain the constant reaction time of 120 ms. This procedure was repeated for all collected samples.

### 3.2. Jet Stirred Reactor(JSR)

The oxidation of *n*-Pch was studied in a jet stirred reactor (JSR) at KAUST. Species profiles for *n*-Pch and intermediates (CO, C<sub>2</sub>H<sub>4</sub>, C<sub>3</sub>H<sub>6</sub>) were analyzed at atmospheric pressure at a range of temperatures (500–800 K) and equivalence ratios ( $\phi = 0.5, 1.0, 2.0$ ). The JSR experimental setup consists of a 76 cm<sup>3</sup> spherical quartz reactor with four nozzles of 0.3 mm diameter to attain homogeneity of species and temperature distribution. The JSR is connected to upstream and downstream quartz tubes of diameter 25.4 mm. *n*-Pch was stored in a 10 ml syringe and was injected using a syringe pump at a constant flow rate. After vaporization, fuel was diluted with N<sub>2</sub> and mixed with O<sub>2</sub> at the JSR entrance, and the flow rate was regulated with a multi-gas controller (MKS) mass flow meter. The reactor and part of the upstream and downstream quartz tubes were symmetrically placed in an electrical heating furnace to promote oxidation reactions. The furnace temperature was monitored via a K-type thermocouple inserted into a quartz shield [72]. The quartz tubes (upstream and downstream) located outside the furnace were heated with electrical heating tape and maintained at 393 K using stainless-steel K-type thermocouples and temperature controllers.

Stable intermediates and fuel and oxidizer species were sampled by a sonic probe connected to the vacuum suction pump to prevent further reactions. All downstream tubing was heated to

373 K to avoid condensation. Gas composition was analyzed using a refinery gas analyzer (RGA), a uniquely designed gas chromatography system, coupling a flame ionization detector (FID) and a thermal conductivity detector (TCD) where helium was used as carrier gas. Capillary columns (Molecular Sieve 5A, 2 ft and 4 ft Unibeads 1S, HP-Al/S and DB-1) were used for species quantification including *n*-Pch, ethene, oxygen, carbon monoxide, carbon dioxide, and propene. The uncertainty in the measurement of fuel/oxygen concentration and intermediates is 10% and 20%, respectively. The uncertainty in temperature measurement is  $\pm 25$  K. O<sub>2</sub> and N<sub>2</sub> gasses used during the experiments had purity over 99.99%. The JSR residence time was set to two seconds at atmospheric pressure. Further details about measurement methods and the apparatus are provided in [73]

### 3.3. Shock tube and rapid compression machine

High-pressure ignition delay time measurements of *n*-Pch were conducted using the shock tube and rapid compression machine facilities at KAUST. IDT measurements were performed over a wide range of experimental conditions, spanning the temperature range of 625 to 1100 K at two pressures, 20 and 40 bar and two equivalence ratios, 0.5 and 1. The shock tube (ST) and rapid compression machine (RCM) facilities at KAUST have been extensively reported in the literature [74, 75] and hence only a brief description is provided here.

The ST employed in this study consists of double diaphragm mid-section configuration, which allows improved control of the diaphragm burst pressure and higher control of the thermodynamic conditions behind the reflected shock wave. The shock tube is constructed with stainless steel and consists of two sections, namely driver and driven sections of similar length (6.6 m) and diameter (10 cm). The shock tube and mixing tank, along-with the mixing manifold, were heated to 100 °C to avoid any condensation of fuel on the inner walls. Near the end-wall of the driven section, six dynamic pressure transducers were installed to measure the incident shock speed. The measured shock speed and the *n*-Pch/oxidizer mixture's thermodynamic properties were utilized to calculate reflected shock temperature and pressure using one-dimensional shock jump equations. During the measurements, ignition delay time was computed using pressure signal and OH\* chemiluminescence measurements through the sidewall and end-wall ports. Estimated uncertainty in the reflected shock temperature/pressure is <1% and the estimated uncertainty in the ignition delay times is ~ 20%. Gradual pressure rise behind the reflected shock wave,  $dp/dt$ , was measured to be 3% / ms; there-

**Table 1**

Equivalence Ratio, $\phi$	0.27	0.27	0.27	± 0.05
Temperature (K)	550–850	550–850	550–850	± 5.0
Pressure (atm)	8.000	8.000	8.000	± 0.025
Residence Time (ms)	120	120	120	± 1.0

fore, a 3%  $dp/dt$  was imposed on zero-dimensional kinetic simulations [26].

The RCM facility at KAUST is equipped with a twin-opposed piston design that facilitates a higher degree of mechanical balance and shorter compression time than a single-piston configuration. The reaction chamber is 50.8 mm in diameter and stroke length of 169 mm per piston, allowing a compression ratio of 16.8:1. The pistons are equipped with a fast pneumatic compression system that helps achieve compression times (final 50% of compression stroke) of ~ 3 ms. The compressed gasses pressure was monitored using a pressure transducer (Kistler 6045) mounted on the combustion chamber during the compression and ignition process. To avoid forming roll-up vortices inside the core of the reaction chamber, creviced pistons with ~ 10% of the post-compression volume were employed [27]. Post compression heat loss from the RCM was accounted for by using non-reactive volume profiles [28] during chemical kinetic simulations. Estimated uncertainty in the RCM ignition delay measurements is ~ 15%. The purity of gasses used during these measurements are CO<sub>2</sub>: 99.995%, N<sub>2</sub>: 99.995%, O<sub>2</sub>:99.995% with traces of Ar (<1 ppm), N<sub>2</sub> (<1 ppm), Moisture (<2 ppm). Non-reactive RCM volume profiles required for simulations and mixture fractions are provided as Supplementary Material.

## 4. Results and discussion

### 4.1. Pressurized Flow Reactor(PFR): experimental and modelling

Oxidation of *n*-Pch was studied in the Drexel PFR at two nearly identical experimental conditions, as shown in Table 1. The results are the average of both experiments with the uncertainties being ±1 standard deviation for stable intermediates measured with the GC/MS/FID, and equal to the equipment uncertainty for carbon monoxide, carbon dioxide, and oxygen.

During the PFR study (i.e., <850 K), carbon monoxide formation is an indicator of low-temperature oxidation reactivity as there is little conversion of CO to CO<sub>2</sub> [76] at low temperatures. Fig. 8 presents a reactivity map with the molar fractions of carbon monoxide, carbon dioxide, molecular oxygen, and *n*-Pch plotted concerning temperature. The oxidation behavior of *n*-Pch exhibits classical NTC behavior. The start of NTC for *n*-Pch, as indicated by the temperature at which the molar fraction of CO peaks and begins to decrease, occurs at approximately 700 K with CO production of roughly 770 ppm. Also, carbon dioxide levels at NTC start is about 180 ppm, which is similar to previous PFR experiments performed on straight-chain alkanes such as *n*-decane and *n*-dodecane [70,77], as well as the previously studied methyl-alkylated alkane, 2,7-DMO [31]. Namely, the carbon dioxide profile tracks the carbon monoxide profile over the low to intermediate temperature regime, but at lower levels on the order of 25–35% of the CO molar fraction. Lastly, at NTC start where maximum reactivity exists corresponds to a minimum in the *n*-Pch and molecular oxygen molar fraction profile. At NTC start, the *n*-Pch molar fraction is approximately 115 ppm which translates to 86% fuel conversion. The O<sub>2</sub>

**Fig. 8.** Pressurized flow reactor simulations: Species profile from experiment and Chemkin pro simulations for *n*-Pch, O<sub>2</sub>, CO, CO<sub>2</sub>.

molar fraction is about 40,000 ppm which corresponds to approximately 5% of the reactant O<sub>2</sub> being consumed suggesting that C–H remains in fuel fragments.

These trends are like those observed in the related *n*-Bch oxidation study [38] as shown in Fig. 3 in [38]. Both *n*-Pch and *n*-Bch studies were for 8 bar pressure, 550–850 K, 120 ms residence time, but different fuel loading as discussed below. The NTC start temperature for *n*-Pch shifted approximately 20 °C higher than *n*-Bch. The trend follows results observed by Kurman et al. [77], in which NTC start occurred at 675 K for *n*-dodecane, and NTC start occurred at 695 K *n*-decane. This illustrates the general observation that NTC start for smaller and simpler chemical structures (e.g., *n*-Pch, and *n*-decane) occurs at higher temperatures as compared to larger and more complex chemical structures (e.g., *n*-bch, and *n*-dodecane) for low to intermediate temperature regime oxidation. Also, the peak CO level for *n*-Pch was roughly 800 ppm at approximately 690 K and around 1600 ppm at approximately 670 K for *n*-Bch. This translates to about 11% of the *n*-Pch fuel carbon converting to produce CO at approximately 690 K (i.e., NTC start temperature for *n*-Pch) and about 14% of the *n*-Bch fuel carbon converting to produce CO at around 670 K (i.e., NTC start temperature for *n*-Bch). This indicates peak CO levels are highly dependent on initial fuel loading since *n*-Pch was initially 826 ppm and *n*-Bch was initially 1082 ppm. For comparing different fuels' reactivity at other fuel loading conditions, the NTC start temperature is suggested as a fuel reactivity indicator since it is strongly dependent on the oxidation chemistry of a particular fuel rather than fuel loading.

During these experiments seventy-seven stable intermediate species were identified and quantified using the GC/MS/FID system and CO/CO<sub>2</sub>/O<sub>2</sub> detector during both *n*-Pch experiments. The carbon balances for all sample temperatures were greater than 90%. The minimum occurring at 700 K. Supplementary material lists the sixty-two stable intermediate species measured at molar fractions greater than approximately one ppm and their corresponding uncertainties. The fifteen stable intermediate species measured at molar fractions less than approximately 1 ppm included: 1-hexene; *n*-butylcyclohexane; 1,3-pentadiene; 2-butene; 2-methylcyclohexyl propionate; cyclohexene, 4-butyl; cyclohexene, 1-butyl; cyclohexanol, 3-methyl-2-(1-methylethyl)- (1a,2a,3a); cis-7-decen-1-ol; cyclohexanone, 2-(2-butynyl)-; 1,3-isobenzofurandione, hexahydro-, trans-; 2,2-bifuran, octahydro-; cyclohexanone, 2-butyl; 2-(4-methylcyclohexylidene)-1-propanol; 9-Ethylbicyclo(3.3.1)nonan-9-ol. The entire list of species quantified during these experiments is included in the supplementary material.

Another observation in PFR measurements is mismatch of fuel concentrations between 550 K and 850 K. The Pressurized Flow Re-

Fig. 9. Pressurized flow reactor simulations: Species profile from experiment and Chemkin pro simulations for ethene propene, 1-butene.

Fig. 10. Pressurized flow reactor simulations: Species profile from experiment and Chemkin pro simulations for aldehydes: propanal and 2-propenal.

actor (PFR) experiment begins at the higher temperature of 850 K and is reduced to the lower temperature of 550 K over time at approximately 50 K increments. The reason for less fuel recovered at the lower temperatures is likely due to the gas chromatograph/mass spectrometer (GC/MS) drift over time.

Chemical kinetic simulations for PFR oxidation were carried out with the kinetic model developed in this study using Chemkin Pro-ver. 19.2 [78]. The energy equation was solved for the plug flow reactor model with single inlet and outlet stream under adiabatic conditions using the reactor geometry, experimental conditions and initial species concentration to simulate the experiments accurately. In Fig. 8, we compare experimental and simulation species profiles for *n*-Pch,  $O_2$ , CO and  $CO_2$ . The simulated reactivity profile of *n*-Pch simulations closely predicts the consumption of *n*-Pch across the entire measurement range except for over prediction of fuel consumption in the NTC region. Consistent with higher predicted fuel consumption in the NTC region, the  $O_2$  profile also shows higher consumption in the NTC region. The model predicts higher CO before, and in the NTC region, however, the predicted concentration of CO is lower at the start of NTC.

In Fig. 9, experiment and simulation results of various alkene intermediates produced during oxidation of *n*-PCH are presented. During the oxidation process, short chain alkenes observed are i.e. ethene, propene and 1-butene and no larger alkene concentrations were measured.

**Fig. 18.** Comparison of experimental data from Dubois et al. [28] and the ignition delay predictions using the *n*-Pch kinetic model proposed in this study. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

The computed species profile of propene captures the experimental trend and the overall peak concentration produced; however, it shows a shift towards high temperature, resulting in lower production rates before the NTC region. Also, towards the high temperature end, the concentration of propene is overpredicted. 1-Butene was observed in low concentrations which is well predicted by the model except at 650 K. The concentration of ethene is largely over predicted in the intermediate temperature regime. The concentrations of these alkenes produced is minor compared to significant intermediates and products (i.e., CO, CO<sub>2</sub>) and are not expected to have any significant effect on combustion characteristics of *n*-Pch, so the kinetic model was not tuned further to improve their prediction.

The developed kinetic scheme also considers production and consumption of smaller aldehydes during the oxidation of *n*-Pch. Several aldehydes were measured, including acetaldehyde, propanal, 2-propenal, butanal, and 1,3,5-trioxane. However, the kinetic model only includes propanal and 2-propenal production and consumption pathways. As shown in Fig. 10, the computed concentrations of propanal overpredict PFR measurements in the low-temperature regime and underpredict the PFR measurements at NTC start. The computed species profile of 2-propenal cap-

the experiment in Fig. 17. The kinetic model well represents the experimental data at low temperature, high temperature and part of the NTC region. The kinetic model to some extent overpredicts the shock tube ignition delay in the high temperature range.

In addition to the data acquired in this study, the developed kinetic model is also compared to ignition delay measurements conducted at 10 bar from Dubois et al. [28] the comparison is presented in Fig. 18. The comparison between the experimental data and the model predictions highlights that the ignition delay predicted by the model is a factor of 2.5 higher over the temperature

range at all equivalence ratios. These comparisons also point towards lack of reliable kinetic data for *n*-Pch combustion especially in the high temperature region.

#### 4.4. Chemical kinetic analysis

Flux analysis has been conducted at 20 bar for 650 K, 850 K, 1050 K and  $\varphi = 0.5, 1.0$  to identify the crucial reactions involved in determining the ignition characteristics of *n*-Pch. These experimental conditions covered the entire range of low, intermediate and high-temperature ignition at two different equivalence ratios.

In addition to the flux analysis, ignition delay sensitivity analysis was also conducted at 20 and 40 bar at  $\varphi = 0.5$  and 850 K, where the definition of sensitivity coefficient ( $S_i$ ) is:

$$S_i = \frac{(\tau_{\text{ign}(2k_i)} - \tau_{\text{ign}(k_i/2)})}{(2k_i - k_i/2)} \frac{k_i}{\tau_{\text{ign}(k_i)}} \\ S_i = \frac{(\tau_{\text{ign}(2k_i)} - \tau_{\text{ign}(k_i/2)})}{1.5\tau_{\text{ign}(k_i)}} \quad (1)$$

where,

$\tau_{\text{ign}(2k_i)}$  = ignition delay prediction when  $i$ th reaction with rate constant  $k_i$  is multiplied by 2

$\tau_{\text{ign}(k_i/2)}$  = ignition delay prediction when  $i$ th reaction with rate constant  $k_i$  is divided by 2

In Fig. 19, the flux analysis of  $n$ -Pch has been presented at 15% fuel consumption, 20 bar and 650 K, 850 K, 1050 K. At all three temperatures, fuel molecule is predominantly consumed through H-atom abstractions leading to the production of seven fuel radicals. At 650 K, the fuel radicals are further consumed by first  $\text{O}_2$  addition, leading to hydroperoxyalkyl radical via internal H atom abstraction from the site adjacent to the ring. Thus, another  $\text{O}_2$  molecule is added to the radical site, eventually leading to ketohydroperoxide formation and its eventual decomposition. At 650 K, only pathways are presented for one dominant fuel radical; however, at 650 K being consumed through low-temperature oxidation pathways. Another observation is that the dependence of these pathways on equivalence ratio is minimal as earlier highlighted in Fig. 16 and 17. At 850 K, the fuel molecule undergoes  $\text{O}_2$  addition at radical sites to produce  $\text{RO}_2$  radicals which further exhibits low-temperature chain branching to eventual production and consumption of ketohydroperoxides. At this temperature  $\text{RO}_2$  also exhibits competing pathways to produce cyclic alkenes via QOOH decomposition due to the increase in temperature from 650 K to 850 K.

Eventually, at 1050 K, the low-temperature branching is replaced by  $\beta$ -scission, fuel radical isomerization, cyclic alkene and cyclic ether formation. The fuel radicals thus produced are consumed by  $\beta$ -scission producing cyclic alkenes and alkenyl radicals further consumed by H-atom abstraction and  $\beta$ -scission. The H-atom abstraction reaction's dominant products are R5, R6 and R7 (in Fig. 2), which are also the most significant pathway as identified in the sensitivity analysis in Fig. 20. The sensitivity analysis identifies reactions playing a significant role in determining ignition delay time or reactivity of the system at these conditions. As per Eqn. (1) and an increase in the magnitude of the A-factor of the reactions with sensitivity coefficient in positive directions will inhibit the reactivity of the system by increasing the ignition delay; while increasing the A-factor of reactions with negative sensitivity coefficients will promote reactivity, thus decreasing the ignition delay time. In Fig. 20, apart from G69, there are some other notable reactions such as decomposition of hydroperoxide ( $\text{H}_2\text{O}_2$ ) to two hydroxyl radicals (OH) (G3879) and formation of ketohydroperoxide from peroxyhydroperoxyalkyl radical (G3651). While decomposition of  $\text{H}_2\text{O}_2$  is a significant source of hydroxyl radicals controlling the ignition process, the formation and eventual decomposition of ketohydroperoxides also promotes ignition by releasing hydroxyl radicals. At 40 bar, higher yield of fuel radical  $\text{C}_3\text{H}_7\text{S}_2\text{XC}_6\text{H}_{10}$  is observed as shown in Fig. 20 which further leads to the production of higher concentrations of intermediates in the low-temperature chain branching process including production and decomposition of ketohydroperoxides. This higher branching ratio leads to increased reactivity at 40 bar, which results in lower ignition delay and suppressed NTC behavior. Another explanation of this shift in NTC behavior could be derived

from the method of experimental measurements. The structure of species discussed in the sensitivity analysis in Fig. 20 is depicted in Fig. 21.

## 5. Summary and conclusion

This work presents a detailed experimental, kinetic modelling and quantum chemistry study of  $n$ -propylcyclohexane, a crucial component of jet fuels. The oxidation of  $n$ -propylcyclohexane was studied experimentally using several experiments including jet stirred reactor (JSR), pressurized flow reactor (PFR), shock tube (ST) and rapid compression machine (RCM) covering a wide range of pressure, temperature and equivalence ratios. Further, a detailed chemical kinetic model comprising of low, intermediate and high-temperature kinetics was developed. The reaction rates for  $n$ -propylcyclohexane consumption were estimated based on analogies with existing and analogous species mechanisms. The thermochemistry for several new species was also estimated by quantum chemistry methods and group additivity approach. The kinetic model predictions were compared against the experimental data with satisfactory agreements for speciation data from the JSR and PFR measurements for several major species. There is room for improving the kinetic model for several minor intermediates measured in these experiments. Experimental and simulated ignition delays were also compared. The model satisfactorily describes the ignition characteristics of  $n$ -propylcyclohexane in the entire region with exception of longer predicted ignition delay time in high-temperature and in the NTC region. The model was also compared with experimental ignition delay data at 10 bar from Dubois et al.[28], and the model was found to over predict the ignition delay times at all equivalence ratios, highlighting the need for calculations and measurements of reliable reaction rates describing  $n$ -propylcyclohexane kinetics.

This work provides a comprehensive investigation of  $n$ -propylcyclohexane combustion chemistry and will prove instrumental in studies of analogous alkylated cyclic alkanes.
